Abstract

Background
The A3243G point mutation in mitochondrial DNA (mtDNA) is associated with MELAS (mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes) and MIDD syndromes (maternally inherited diabetes and deafness). Both MELAS and MIDD patients can present with visual symptoms due to a retinopathy, sometimes before the genetic diagnosis is made.

Case presentation
Patient 1: 46 year-old woman with diabetes mellitus and hearing loss was referred for ophthalmological evaluation. Visual acuity was 20/20 in both eyes. Fundus examination showed bilateral macular and peripapillary hyperpigmented/depigmented areas.

Patient 2: 45 year-old woman referred for recent vision loss in her left eye. History was remarkable for chronic fatigue, migraine and diffuse muscular pain. Visual acuity was 20/20 in her right eye and 20/30 in her left eye. Fundus exhibited several nummular perifoveal islands of retinal pigment epithelium atrophy and adjacent pale deposits in both eyes.

Retinal anatomy was investigated with autofluorescence, retinal angiography and optical coherence tomography. Retinal function was assessed with automated static perimetry, full-field and multifocal electoretinography. Genetic testing of mtDNA identified a point mutation at the locus 3243.

Conclusion
Observation of RPE abnormalities in the context of suggestive systemic findings should prompt mtDNA testing.

Keywords: MELAS, MIDD, macular dystrophy, A3243G
Background

The A3243G mitochondrial DNA (mtDNA) point mutation has been associated with a wide range of clinical manifestations, including MELAS syndrome (mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes) and MIDD syndrome (maternally inherited diabetes and deafness).[1][2]

The ocular findings of MELAS include pigmentary retinopathy, external ophthalmoplegia, ptosis and posterior subcapsular cataract.[3][4] The main ocular feature in MIDD syndrome is a pigmentary retinal dystrophy also described as a macular pattern dystrophy.[5][6] The retinopathies associated with both syndromes have heterogeneous presentations with variable degrees of retinal pigment epithelium atrophy and hyperpigmentation at the posterior pole.[3][5][7]

De Laat et al. proposed a classification system based on 4 grades: fine pigment abnormalities (grade 1), yellowish or mildly pigmented deposits (grade 2), chorioretinal atrophy outside the fovea (grade 3) and atrophy affecting the fovea (grade 4).[8]

Rath et al. described two distinctive phenotypes of retinopathy.[9] The first phenotype is characterized by a discontinuous perifoveal atrophy that assumes a circumferential distribution. With time, the areas of atrophy will coalesce into a ring of pericentral atrophy. Occasionally, pale deposits can be present at the level of the retinal pigment epithelium (RPE), the RPE can exhibit a granular appearance, and subretinal pigment clumping can be found adjacent to the areas of atrophy.

The second phenotype is consistent with a pattern dystrophy. It includes granularity of the RPE, pale deposits and pigment clumping at the level of the RPE, without any significant atrophy.

We report two patients with the mtDNA A3243G point mutation who each present one of the previously described retinal phenotypes.
Case presentation

Patient 1

A 46 year-old woman was referred for ophthalmological evaluation of an unspecified maculopathy. Insulin-dependent diabetes mellitus was diagnosed at age 20. The patient had bilateral sensorineural hearing loss since age 41 and was wearing a hearing aid. Migraine was present since age 26. Family history revealed that her mother died from stroke at age 43. Five out of six maternal aunts and uncles were affected by diabetes mellitus and/or hearing loss.

Best-corrected visual acuity was 20/20 in both eyes. Fundus examination revealed bilateral hyperpigmented lesions surrounding the macula and the optic disc, associated with depigmentation areas of the RPE. Fundus autofluorescence (Heidelberg Retina Angiograph; Heidelberg Engineering, Heidelberg, Germany) was characterized by a diffuse speckled appearance of the macula (Figure 1). Fluorescein angiography displayed a mottled appearance of the posterior pole with adjacent areas of hyper- and hypofluorescence, indicating defects of the RPE and pigment deposits, respectively. Spectral-Domain Optical Coherence Tomography (SD-OCT, Spectralis, Heidelberg Engineering, Heidelberg, Germany) scans taken through the hyperpigmented lesions showed a hyperreflective dome-shaped change that seemed to originate from the RPE (Figure 2).

Results from automated static perimetry (Octopus 300, program G1, Haag-Streit, USA), scotopic and photopic full-field electroretinography (ERG) were normal in both eyes. Multifocal ERG showed a moderate and diffuse depression of potentials in both eyes. Magnetic resonance imaging (MRI) of the brain was unremarkable. Genetic testing of mtDNA identified a point mutation at the locus 3243 with 35% heteroplasmy in leucocytes.
Patient 2

A 45 year-old woman was referred for recent vision loss in her left eye in the context of unusual retinal findings. She had short stature and hearing difficulties were noticed since age 28. There was no history of diabetes mellitus. Personal history revealed chronic fatigue, migraine, diffuse muscular pain and episodes of vomiting for the past 3 years. She was also treated for a depressive state.

Family history revealed that her mother suffered from both diabetes mellitus and hearing loss. Her sister was diagnosed with a psychiatric disorder and suffered from recurring seizures.

Best-corrected visual acuity was 20/20 in her right eye and 20/30 in her left eye. Fundus examination revealed several circumferential perifoveal islands of atrophy and adjacent pale deposits in both eyes. Autofluorescence was decreased inside the atrophic areas, and was increased in the areas corresponding to the deposits. The retina surrounding the atrophic patches demonstrated a speckled autofluorescence (Figure 3). Fluorescein angiography showed window defects in the area of the atrophy and a blocking effect by the pale deposits. On SD-OCT the central foveal anatomy was relatively preserved, with parafoveal zones of attenuation of the outer layers corresponding with chorioretinal atrophy zones (Figure 4).

Results from automated static perimetry (Octopus 300, program G1, Haag-Streit, USA) and scotopic and photopic full-field ERG were within normal limits in both eyes. Multifocal ERG showed slightly decreased potentials in a pericentral zone in both eyes. Brain MRI was normal. Genetic testing of mtDNA extracted from a muscular biopsy identified a point mutation at the locus 3243, and demonstrated 71% of heteroplasmy. A diagnosis of MELAS was given.
Discussion

We report two patients harboring the mtDNA A3243G point mutation but who exhibited two different retinal phenotypes. Namely, the degree of RPE changes was significantly different between our two patients.

According to existing studies, whether the various retinal findings associated with this mtDNA point mutation are different evolutive stages or correspond to distinct phenotypes is not fully understood.

Mitochondrial disorders lead to a decreased production of ATP. The failure to meet the cellular energetic needs will result in a clinical specific phenotype depending on the affected cells. The clinical spectrum of mitochondrial disorders is broad. However, tissues with a high metabolic demand are typically affected. An outer retinopathy could result from a primary dysfunction of the photoreceptors, a primary dysfunction of the RPE, or a dysfunction of both retinal layers. The RPE is responsible for maintenance of photoreceptor function through continuous phagocytosis, recycling, and nourishment of outer segments. The photoreceptors are constantly degraded and resynthesized, and contain clusters of mitochondria within their inner segments. Whether these two cell layers are equally susceptible to the effects of the A3243G mtDNA mutation, or whether the photoreceptor damage is a consequence of the RPE disease, is not known.

Rummelt et al. described retinal histopathologic findings in a patient with MELAS and severe retinal dystrophy. At the posterior pole, RPE cells were depleted of apical microvilli, melanosomes and phagosomes, and contained abnormal mitochondria. Mitochondria in the inner photoreceptor segments were also abnormal and the outer segments were atrophic. Retinal pigment epithelium and photoreceptor cells in the retinal periphery were unaffected.
The two cases presented here illustrate that the severity of systemic and ocular phenotypes could be related. Indeed, both retinal and systemic manifestations were milder in Patient 1 than in Patient 2. Patient 1 might then represent a milder form of A3243G-associated disease.

Variability of phenotypes associated with mtDNA mutations is well recognized.[10] Such a variation in the phenotypic appearance is presumed to be a consequence of the variable proportions of mutated and normal mtDNA between patients, but also between different tissues within a single individual. This is a characteristic feature of mitochondrial disease known as heteroplasmy.

Latvala et al. evaluated 26 patients with A3443G mtDNA mutation and correlated the presence of RPE abnormalities to the severity of the systemic phenotypes.[12] They showed that both the severity of the systemic disease and the degree of mutant heteroplasmy in muscle correlate positively with RPE abnormalities. The risk of RPE abnormalities was almost 3-fold higher in patients who harbored >68% mutant heteroplasmy in muscle compared to those below these limits. Hence, RPE abnormalities appear to be a retinal manifestation associated with more severe disease phenotypes.

De Laat et al. analyzed 25 patients with the A3243G mutation and retinal abnormalities.[8] The retinal abnormalities were classified into four grades of severity, from fine pigment abnormalities to profound chorioretinal atrophy. The severity of retinal dystrophy was not correlated with heteroplasmy levels measured in the urinary epithelial cells, leukocytes and buccal saliva. There were no correlation between the severity of the retinal dystrophy and the overall disease involvement. These results are in contradiction with the study by Latvala et al. in which, remarkably, heteroplasmy was assessed from muscle biopsies in all patients.
Smith et al. found that among 13 subjects with MIDD, pigmentary retinal dystrophy and abnormal ERG findings were more frequent in patients over 40 years of age and in those with diabetes duration longer than 5 years.[5] In this study the presence of systemic features of A3243G disease in all patients with retinal dystrophy, and the comparatively mild phenotypes of two subjects with no retinal disease, also support the hypothesis of a correlation between systemic and ocular phenotypes as a consequence of heteroplasmy. However, age and duration of diabetes were not correlated with severity of the retinal pigment abnormalities.

Further, Massin et al. analyzed 33 patients with MIDD, and found no significant correlation between severity of macular dystrophy and patients’ age or duration of diabetes (Table 1).[6]

**Conclusion**

Variable degrees of RPE changes are observed among patients with the A3243G mtDNA mutation. The correlation of theses findings with the systemic involvement remains unclear. Observation of RPE abnormalities in the context of suggestive systemic findings should prompt mtDNA testing.
**Consents**

Written informed consent was obtained from the patients for publication of this Case report and any accompanying images. A copy of the written consent is available for review by the Editor of this journal.

**List of abbreviations**

ERG: electroretinography

MELAS: mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes

MIDD: maternally-inherited diabetes and deafness

MRI: magnetic resonance imaging

mtDNA: mitochondrial DNA

RPE: retinal pigment epithelium

SD-OCT: spectral-domain optical coherence tomography

**Competing interests**

The authors declare that they have no competing interests.

**Authors' contributions**

AD: data collection, analysis and interpretation of data, review of the literature and manuscript draft.

AM: acquisition of data and help to draft the manuscript.

F-XB: acquisition of data, coordination, clinical advice and critical revisions

Figure legends

**Figure 1.** Color fundus photograph and fundus autofluorescence of Patient 1. A, B, Color fundus photograph of patient 1. Note the hyperpigmented lesions surrounding the macula and the optic disc, associated with depigmentation areas of the retinal pigment epithelium. C, D, Fundus autofluorescence of the same patient. The hyperpigmented spots correspond to mainly increased autofluorescence, whereas the hypopigmented spots correspond a decreased granular autofluorescence signal.

**Figure 2.** Fluorescein angiography and SD-OCT of Patient 1. A, B, Fluorescein angiography showed blockage of background fluorescence in the areas of hyperpigmentation and hyperfluorescence due to retinal pigment epithelium window defects in the depigmented areas. C, D, On SD-OCT scans taken through the planes indicated by the green arrows, hyperpigmented areas corresponded to a hyperreflective dome-shaped lesion that seemed to originate from the retinal pigment epithelium.

**Figure 3.** Color fundus photograph and fundus autofluorescence of Patient 2. A, B Color fundus photograph of patient 2. Note the circumferential perifoveal patches of atrophy and the adjacent pale deposits. C, D, Fundus autofluorescence of the same patient showed decreased autofluorescence signal inside the atrophic areas, and increased signal in the areas corresponding to the deposits, which surrounded both the macula and optic disc.

**Figure 4.** Fluorescein angiography and SD-OCT of Patient 2. A, B, Fluorescein angiography of the patient 2, showed window defects in the area of the atrophy and a
blocking effect by the pale deposits. C, D, On horizontal OCT scans taken through the planes indicated by the green arrows, the outer retina was markedly attenuated in the zones of chorioretinal atrophy.
