Key words: Beck Depression Inventory, melancholic depressive symptoms, non-melancholic depressive symptoms, population-based, vitamin B₁₂
Abstract

Background
An association between vitamin B_{12} levels and depressive symptoms (DS) has been reported in several epidemiological studies. The purpose of this study was to evaluate vitamin B_{12} levels in population-based samples with melancholic or non-melancholic DS as the relationship between vitamin B_{12} levels and different subtypes of DS has not been evaluated in previous studies.

Methods
Subjects without previously known type 2 diabetes, aged 45-74 years were randomly selected from the National Population Register as a part of the Finnish diabetes prevention programme (FIN-D2D). The study population (N = 2806, participation rate 62%) consisted of 1328 men and 1478 women. The health examinations were carried out between October and December 2007 according to the WHO MONICA protocol. The assessment of DS was based on the Beck Depression Inventory (BDI, cut-off ≥10 points). A DSM-IV criteria based summary score of melancholic items in the BDI was used in dividing the participants with DS (N = 429) into melancholic (N = 138) and non-melancholic DS (N = 291) subgroups. In the statistical analysis we used chi-squared test, t-test, permutation test, analysis of covariance, multivariate logistic regression analysis and multinomial regression model.

Results
The mean vitamin B_{12} level was 331±176 pmol/L in those without DS while the subjects with non-melancholic DS had a mean vitamin B_{12} level of 324 ± 135 pmol/L, and those with melancholic DS had the lowest mean vitamin B_{12} level of 292±112 pmol/L (p<0.001 after adjusted for age, sex, use of antidepressive medication and chronic diseases sum index). The adjusted difference of vitamin B_{12} levels between the non-melancholic and the melancholic group was 33 pmol/L (95%CI 8 to 57, p = 0.008). Melancholic DS and vitamin B_{12} levels showed an independent linearly inverse association. The relative risk ratio (RRR) for melancholic DS was 2.75 (95%CI 1.66 to 4.56) in the lowest vitamin B_{12} level tertile versus the highest (p for linearity <0.001) when those without DS formed the reference group. The RRR in the non-melancholic subgroup was nonsignificant.

Conclusions
The vitamin B_{12} level was associated with melancholic DS but not with non-melancholic DS.
Depression is a global public health problem particularly in developed countries. Recently, the World Health Organization estimated that unipolar depressive disorder remains one of the leading causes of total disability adjusted life years (DALY’s) worldwide [1]. It accounts for 8% of total DALY’s in the Americas and 6% in Europe [2]. Overall, the 12-month and lifetime prevalence rates of depression are approximately 12% and 24% among U.S. men and women, respectively [3].

A wide array of etiological hypotheses has been suggested to underlie depression. Of the biological hypotheses, the monoamine hypothesis proposes an important etiological role for serotoninergic or noradrenergic dysfunction in depression [4]. Besides folate, vitamin B12 is involved in single-carbon transfer reactions needed for the production of serotonin and other monoamine neurotransmitters [5]. Vitamin B12 deficiency may also result in the accumulation of homocysteine, which has been suggested to lead to exito-toxic reactions and may enhance depression [6-7]. Homocysteine can be remethylated to methionine, which requires vitamin B12 [8]. Methionine is the immediate precursor of S-adenosylmethionine (SAM), the methyl donor of numerous methylation reactions in the brain, many of which are directly involved in the synthesis and metabolism of dopamine, norepinephrine and serotonin [9]. These findings form a plausible link between vitamin B12 and mood, and may also indicate that the association between depression and vitamin B12 could be mediated through monoamine synthesis.

In clinical studies, lower vitamin B12 levels have been found to be associated with severe depression [10-11]. Low serum vitamin B12 levels are also detected in approximately 20% of psychiatric patients [12]. On the other hand, high vitamin B12 levels were associated with a good treatment outcome in patients with major depressive disorders in a clinical setting [13]. However, a small randomised trial found no improvement in depression after the administration of vitamin B12 as an adjuvant [14].

The three cross-sectional studies and one prospective population-based study that have reported a connection between vitamin B12 levels and DS or depressive disorders were conducted on older adults [15-18]. In the Women’s Health and Aging Study B12 deficiency was associated with a two-fold increased risk of severe depression [15]. The Rotterdam Study found that B12 deficiency was independently associated with depressive disorder among older adults [16]. A study among Chinese older adults also found a correlation between deficient levels of vitamin B12 and greater risk of DS [18]. The only existing community-based prospective study reported that lower levels of vitamin B12 at baseline were associated with a higher risk of incident of depression on 2-3 year follow-up among older Korean people [17]. However, previous results have been somewhat inconsistent, since some studies, mainly conducted in younger populations, have found no association between vitamin B12 levels and DS or depressive disorders [19-23].

Methods

Study population and the setting of the study

The Finnish type 2 diabetes (FIN-D2D) survey is the implementation project of a national programme for the prevention of type 2 diabetes covering a population of 1.5 million during the years 2003–2008
The specific aims were to improve the screening of people at risk of diabetes and the detection of undiagnosed diabetes, as well as the prevention of diabetes among national population.

A random sample of 4500 subjects without previously known type 2 diabetes, aged 45–74 years, stratified according to gender and 10-year age groups (45–54, 55–64 and 65–74 years), was selected from the National Population Register of Finland in August 2007. The sampling represented three separate geographical areas with both urban and rural populations. The study participants were invited by mail to a health examination. The study population (N = 2806, participation rate 62%) consisted of 1328 men and 1478 women. The participants and the nonparticipants (N = 1694) did not differ with regard to age or gender distribution. The Ethical Committee of the Hospital District of Helsinki and Uusimaa approved the study protocol. All participants gave their written informed consent prior to participation in the study.

Design of the study and measurements

Depressive symptoms

DS were assessed by using the Beck Depression Inventory (BDI), which is a 21-item self-report questionnaire consisting of symptoms and attitudes related to depression [25]. The items are summed in a total score with a range from 0 to 63. The cut-off point for DS was 10, which has been reported to be a feasible instrument for depression screening [26]. It has also been shown to be a useful tool for detecting depressive symptoms in various adult populations [27-32]. Out of the whole study population, 429 (15%) subjects with a BDI score \( \geq 10 \) were identified. In order to examine the effect of the subtype of DS, we used a summary score of melancholic symptoms in the BDI based on the DSM-IV-defined criteria for melancholic depression (sadness, past failure, loss of pleasure, guilty feelings, punishment feelings, loss of interest, irritability, change of sleeping and appetite) in dividing the participants with increased DS into melancholic and non-melancholic depressive symptom subgroups in a similar way that has been published to be useful in several previous studies. The subjects were defined to have DS with melancholic characteristics when the number of melancholic symptoms exceeded the number of non-melancholic symptoms [29,33-35].

Laboratory analysis

The study methods followed the World Health Organization MONICA protocol [36]. After an overnight fast, blood samples were drawn for basic biochemical measurements, including serum vitamin B\( _{12} \). The serum and plasma were separated within one hour by centrifugation at room temperature. The samples were then aliquoted into storage tubes and stored at a minimum of \(-20^\circ\)C. The samples were later transported frozen to the National Institute for Health and Welfare and stored at \(-70^\circ\)C until analyzed at the laboratory of the Disease Risk Unit.

Serum vitamin B\( _{12} \) was measured with an Architect ci82000 analyzer (Abbott Laboratories, Abbott Park, IL) using the Chemiluminescent Microparticle Immuno Assay (CMIA). The reference range was 138-652 pmol/L for the normal serum vitamin B\( _{12} \) level. The interassay coefficients of variation (CV) of B\( _{12} \) vitamin were 6.2% and 5.0% at the levels of 150 pmol/L and 380 pmol/L, respectively.

Other measurements

Height was measured to the nearest 0.1 cm, and weight was measured in light clothing to the nearest 0.1 kg. The body mass index (BMI) was calculated as weight (kg) divided by the square of height (m). Waist circumference was measured midway between the lowest rib margin and the iliac crest. Education was assessed according to years of education. The participants reported their marital status, and
were categorized as married, single, separated or widowed. Employment status was inquired, and the number of employed participants was counted. Current smoking and alcohol consumption were assessed with self-administered questionnaires, and dichotomized (no or yes). Leisure-time physical activity (LTPA) was assessed with the question: “How much physical activity do you practice during leisure-time?” Response categories were: In my leisure-time I 1) read, watch television and do things that do not require physical activity; 2) walk, ride a bicycle or exercise in other ways requiring physical activity for at least four hours a week; 3) have physical activities to maintain my condition such as jogging, cross-country skiing, aerobics, swimming or ball games at least three hours a week; and 4) practice regularly for competitions in running, cross-country skiing, orienteering, ball games, or other heavy physical exercise several times a week. The intensity of LTPA was classified as low (category 1), moderate (category 2) or high (categories 3 and 4) [31]. A chronic diseases sum index was based on the question “Have you had any of the following diseases that have been diagnosed or treated by a doctor in the last 12 months?” The diseases included elevated blood pressure, heart failure, angina pectoris/other cardiovascular event, diabetes, cancer, bronchial asthma/emphysema and rheumatoid arthritis/other arthropathy/spinal diseases. The chronic diseases sum index ranged from 0 to 7 [32]. The use of antidepressive medications was also recorded.

Statistical analysis

The data are presented as means with standard deviations or counts with percentages. Groups were statistically compared using the t-test, permutation test or chi-squared test, as appropriate. The statistical significance between groups was B12 level evaluated by bootstrap type analysis of covariance (ANCOVA) with appropriate contrast Multinomial logistic regression was used to analyze the relative risk ratios (RRR) and their 95% confidence intervals (95% CI) for the presence of non-melancholic and melancholic DS with appropriate contrasts. The multinomial (polytomous) logistic regression model is an extension of the binomial logistic regression model and is used when the dependent variable has more than two nominal (unordered) categories.
Results

The study population (N = 2806) included 429 subjects (15%) with a BDI score ≥10. Table 1 presents the sociodemographic characteristics of the two subgroups with BDI scores <10 or ≥10. Participants with elevated DS were more likely to be female or older, and to have a higher BMI, be less educated, unmarried or unemployed. They also used less alcohol and were less physically active than their non-depressed counterparts. Subjects with increased DS had a higher chronic diseases sum index, and more often used antidepressive medication.

Vitamin B$_{12}$ levels differed between males and females (serum vitamin B$_{12}$ 343 ± 168 pmol/L for females and 312 ± 171 pmol/L for males; p < 0.001). In order to further examine the vitamin B$_{12}$ levels in subjects with depressive symptoms they were subdivided into groups with predominantly melancholic (N = 138) and non-melancholic DS (N = 291). The mean vitamin B$_{12}$ level was 331±176 pmol/L in those without DS while the subjects with non-melancholic DS had a mean vitamin B$_{12}$ level of 324 ± 135 pmol/L, and those with melancholic DS had the lowest mean vitamin B$_{12}$ level of 292±112 pmol/L (p<0.001 after adjusted for age, sex, use of antidepressive medication and chronic diseases sum index)(Figure 1A). The adjusted difference of vitamin B$_{12}$ levels between the non-melancholic and the melancholic group was 33 pmol/L (95%CI 8 to 57, p = 0.008). No difference was found between those without DS and the non-melancholic group (Figure 1A). The vitamin B$_{12}$ levels were significantly lower in the sub-group of melancholic depressive symptoms scoring 10-14 in the BDI. The association of vitamin B$_{12}$ levels with the non-melancholic and melancholic depressive symptoms when subdivided according to the BDI-scores is presented in Figure 1B.

In the multinomial regression analysis there was an independent linearly inverse association between the vitamin B$_{12}$ tertiles and melancholic depressive symptoms: the relative risk ratio (RRR) was 2.75 (95%CI 1.66 to 4.56, p for linearity <0.001) in the lowest vitamin B$_{12}$ level tertile as compared to the highest when those without DS formed the reference group (Table 2). There was no association between B$_{12}$ vitamin tertiles and non-melancholic DS, since the RRR for the lowest vitamin B$_{12}$ level tertile versus the highest was 1.20 (95%CI 0.86 to 1.66, p for linearity 0.28) (Table 2).
Discussion

The novel finding in our population-based study, controlled for multiple potential confounders, was that vitamin B\textsubscript{12} levels showed an independent linearly inverse association with the risk of melancholic DS but not with non-melancholic DS. This result is in line with the monoamine hypothesis of depressive disorders connecting a low vitamin B\textsubscript{12} level with diminished synthesis of serotonin and other monoamines [4]. In our study we observed an approximately three-fold increased RRR for melancholic DS in the lowest vitamin B\textsubscript{12} tertile. Thus, the risk is very much in the same range as the results from a recent study in which vitamin B\textsubscript{12} deficiency appeared to be associated with the occurrence of DS (OR = 2.68) [18]. Two earlier studies reported similar, but somewhat lower risk levels (OR 2.05 and 1.64, respectively) [15-16]. Previously we have reported an association between low folate intake and increasing risk of melancholic DS in this material [35]. Homocysteine was not determined in this study.

All the previous studies showing positive relationships between vitamin B\textsubscript{12} levels and DS or depressive disorders have been conducted among older populations [15-18]. On the other hand, most previous population-based studies not showing an association between vitamin B\textsubscript{12} levels and depressive disorders or DS have been conducted on younger populations than that in our study [20-21,23]. Exceptions are an American and an Australian study that failed to detect this association among older populations [19,22]. These partly inconsistent results may suggest that the age of the study population is important although methodological differences in subject selection and in the measurement methods of depressive symptoms or depression, or in the B\textsubscript{12} status, may also contribute. The distribution of depressive subtypes may also be important as in our study vitamin B\textsubscript{12} levels were lower in the melancholic subgroup. In addition, the severity of DS is also relevant as the difference was significant only in the subgroup of mild depression i.e. 10-14 points in the BDI. Statistical reasons, such as a low number of subjects, or a large variety of vitamin B\textsubscript{12} levels in the sub-group having BDI-scores $\geq 15$ may have affected the significance of the result.

These previous results suggest that the elderly may be more vulnerable to low vitamin B\textsubscript{12} levels. One plausible explanation for these findings is that vitamin B\textsubscript{12} deficiency is more common in the aged. Its prevalence was 12% in the Finnish population (aged 65-100 years) compared to the finding that 5% of Canadians (age 6-79 years) were vitamin B\textsubscript{12} deficient [37-38]. Lifestyle factors such as smoking, alcohol consumption and a vegetarian diet have been linked with an increased risk of vitamin B\textsubscript{12} deficiency in younger adults, [39-40] but no such association was recorded in an aged Finnish population [37]. No specific risk group for lower vitamin B\textsubscript{12} levels in the sub-group having BDI-scores $\geq 15$ may have affected the significance of the result.

The strengths of our study include a large population-based sample containing middle-aged and elderly subjects with a substantial prevalence of DS. The study population was also geographically representative, covering both urban and rural districts in three study areas. In addition, the study data were comprehensively examined, and we used a WHO-based study methodology [36]. The BDI with a cut-off score of 10 points has also been shown to be a useful instrument for detecting DS in various adult populations [27-32].

The way of dividing the DS into melancholic or non-melancholic DS has been applied in several previous studies as well [29,33-35]. However, the criteria that guided the choice for melancholic DS need to be discussed more thoroughly. The chosen melancholic symptoms in the BDI are based on the DSM-IV- defined criteria for melancholic depression [41]. Although e.g. irritability can occur in the non-demented and demented older populations it may be quite near to agitation which is one the criteria for melancholic depression in DSM-IV[41-42]. The fatigue and somatic factor symptoms, including irritability, may be major features of major and in particular of melancholic depression [43]. Irritability may be a symptom of mixed depression as well [44]. In addition, 11-21% of persons in Fin-
land have DS assessed according to the BDI with the same, a rather low cut-off score of 10 points, which is in line with the prevalence of 15% shown in the present study [29,45].

In addition, as the study population was in advanced middle age, the generalizability of the results to younger age groups may be limited. Furthermore, due to the cross-sectional study design, we cannot make inferences of causality. However, cross-sectional studies can produce new associations or hypotheses that can be further studied in observational settings.

Conclusions

In our study we observed that a higher risk of melancholic depressive symptoms was associated with lower vitamin B$_{12}$ levels. Our findings suggest that vitamin B$_{12}$ may contribute to the pathogenesis of DS, although further studies are needed to evaluate the possible associations between DS and vitamin B$_{12}$ levels among populations with different ages and depressive subtypes.

* Gender specific tertiles: Male I > 340 pmol/L, II = 255-340 pmol/L, III < 255 pmol/L; Female I > 380 pmol/L, II = 280-379 pmol/L, III = <280 pmol/L.
# P for linearity.
RRR = relative risk ratio
BDI = Beck Depression Inventory
NmDS = non-melancholic depressive symptoms
MDS = melancholic depressive symptoms
BMI = body mass index
LTPA = leisure-time physical activity
Figure 1A. The association of vitamin B\textsubscript{12} levels with the non-melancholic or the melancholic depressive symptoms and the non-depressive symptoms
Figure 1B. The association of vitamin B\textsubscript{12} levels with severity of the non-melancholic and the melancholic depressive symptoms according to the BDI-scores

Adjusted for age, sex, use of antidepressive medication and chronic diseases sum index

BDI = Beck Depression Inventory
NmDS = non-melancholic depressive symptoms
MDS = melancholic depressive symptoms
