Abstract:
Accidental or intentional subcutaneous and/or intramuscular injection of metallic mercury is an uncommon form of poisoning. Although it does not carry the same risk as mercury vapour inhalation, it may cause destructive early and late reactions. Herein we present the case of a 29-year-old male patient who developed an obsessive-compulsive disorder causing auto-aggressive behaviour with injection of elemental mercury and several other foreign bodies into the soft tissues around the knee about 15 years before initial presentation. As a consequence, the mercury depots and several foreign bodies were resected marginally.
Blood levels of mercury will decrease rapidly following surgery, especially in combination with chelating therapy. In case of subcutaneous and intramuscular injection of metallic mercury we recommend marginal or wide excision of all contaminated tissue to prevent migration of mercury and chronic inflammation. Nevertheless, prolonged clinical and biochemical monitoring should be performed for several years to screen for chronic intoxication.
Introduction:

Metallic mercury is used in the chemical industry as a component of electrical devices or in the manufacture of measuring devices (thermometers, manometers, barometers) [1-5]. Furthermore, it is also a component of amalgam, which is used in dental treatment. The use of mercury in this indication has been the subject of several debates but its toxicity in dental settings has been disproved [6]. Nevertheless, exposure and profile of toxicity depends on the chemical form of mercury (elemental/metallic, inorganic and organic) [3-5, 7, 8].

However, there are several reports in the literature concerning mercury intoxication with Wolfgang Amadeus Mozart as the most prominent possible victim [9]. In most cases, mercury is predominantly absorbed by the respiratory system, particularly by inhalation of the vapour, which is produced at room temperature [4, 8, 10-14]. Following inhalation, mercury damages the lung tissue. A large part of mercury is absorbed by the pulmonary vasculature and then distributed to further organs, additionally. In addition, mercury passes the blood-brain barrier and remains in the nervous system before being oxidized [2, 11, 13, 14].

Subcutaneous and intramuscular injection of elemental mercury is of rare occurrence, although in most cases it may be injected voluntarily in the setting of attempted suicide or in context of psychiatric diseases [1-5, 12, 15-21]. Nevertheless, unintentional injection of mercury is more often observed due to breakage of devices containing this metal. Prasad et al. [15] reported the subcutaneous injection of mercury for ethnic reasons and Lech and Goszcz [8] related a case of mercury intoxication due to ingestion with suicidal intent.

After entering the body, mercury is transported to the liver, the spleen, the kidneys and the brain [1-3, 5, 10-13]. At these locations, mercury is oxidized into divalent mercury
(mercurous and mercuric), which is able to cohere with thiol-groups of enzyme systems, causing tissue damages [1, 2, 5, 13, 14].

Herein we present the case of a 29-year-old male patient who developed an obsessive-compulsive disorder (OCD) causing auto-aggressive behaviour with injection of elemental mercury and other foreign bodies into the left upper and lower leg, 15 years before initial presentation.
Case Presentation:

In 2009, a 29-year-old patient was treated due to an extra-skeletal osteosarcoma of the right thigh. A wide resection was performed for local tumour control and the patient underwent poly-chemotherapy (EURAMOS scheme) and local radiation therapy. About 15 years before this therapy, the patient developed an obsessive-compulsive disorder (OCD) causing auto-aggressive behaviour. In the context of this disease, the patient injected elemental metallic mercury from a clinical thermometer into the soft tissues around the left knee and the upper and lower leg. Furthermore, he pricked 2 spikes and approximately 17 spicules into his thigh during a period of several months and left them in situ. Therefore, an infection of the soft tissues developed, which was treated surgically at an external hospital. Furthermore, a therapy with antidepressant agents was initiated.

In October 2010, 12 months after wide tumour resection, the patient complained about stinging pain in the left thigh and the knee. Plain radiographs and computed tomography of the affected area showed significant volumes of radiopaque foreign material (depots of mercury) and several foreign bodies (2 spikes and 17 spicules; Figure 1a-d). On further questioning, the patient admitted this self injection with metallic mercury and several foreign bodies into the left upper and lower leg several years before. Blood was taken to determine mercury concentration, the C-reactive protein (CRP) and renal function parameters preoperatively. While the renal parameters revealed no pathologic findings, the blood level of mercury (6.80 µg/dl) was 17-fold higher than recommended by the reference laboratory (standard: 0-0.40 µg/dl; Figure 2). The CRP was increased, additionally. There were no neurological symptoms or other signs of systemic poisoning, which are known to occur following long time exposure to elemental mercury.
As a consequence, foreign bodies (2 spikes and 4 spicules) and several mercury depots were resected marginally, except of 13 spicules which had to be left in situ due to the diffuse distribution (Figure 3a-c). Excision of these foreign bodies would have caused too much soft tissue damage of the extensor mechanism, additionally. Furthermore, a therapy with a chelating agent (2,3-dimercaptopropane-1-sulfonate, DMPS) was initiated for 2 months and the therapy with antidepressant agents was continued.

Haematoxylin and Eosin (H&E) stained sections of the specimen showed cicatricial tissue, granulomas caused by foreign bodies, multiple abscesses and black amorphous material surrounded by the foreign-body reaction.

At 6-months follow-up, the patient reported less pain in the left upper leg, the blood concentrations of mercury and CRP had decreased significantly (Figure 2) and he was able to ambulate without any facilities. Clinical and biochemical observation was continued.
Discussion:

Mercury intoxication presents many different symptoms, depending on the form and the route of entry to the organism. Inhalation of metallic or inorganic mercury vapour mainly induces pulmonary disease while chronic inhalation induces neurological or renal disorders [3, 4, 7, 13]. There have been rare cases of acute renal failure, acute respiratory distress and acute chemical pneumonitis [4, 5, 7, 11, 13, 22, 23]. Heise et al. [10] related a case of hemorrhagic colitis secondary to inhalation of mercury vapour and McFee and Caraccio [5] reported abdominal discomfort following mercury ingestion. Nevertheless, ingestion of elemental mercury rarely causes symptoms of intoxication because it is not well absorbed in the gastrointestinal tract [5].

Pulmonic embolism, development of pulmonary empyema, and embolisation to the heart has been reported following intravenous injection [5, 6, 12, 18, 21]. Davey and Benson [21] and Alhamad et al. [4] reported metal dense deposits in the heart following intravenous injection of metallic mercury or inhalation of vaporized mercury. Intra-arterial injection can cause ischemia and/or gangrene secondary to embolisation, additionally [15]. In general, there are no clinical signs of acute systemic intoxication following subcutaneous and intramuscular injection of elemental mercury. An intense local inflammatory reaction with formation of granulomas or aseptic abscess formations may occur several weeks or months following injection [1, 2, 4-6, 12, 15, 20, 21]. Late reactions include foreign body giant cell reaction, fibrosis, granulomas and membranous fat necrosis [5, 12, 15, 24, 25]. Schwarz et al. [26] reported a case of amyotrophic lateral sclerosis 3 years after injuring the hand with a clinical thermometer and Benz et al. [27] described white matter lesions in a 4-year-old girl with chronic intoxication of inorganic mercury secondary to the accidental use of a skin whitening cream.
Nevertheless, following subcutaneous injection of metallic mercury it is essential to prevent systemic absorption and to treat local effects properly. Therefore, prompt excision of subcutaneous deposits has to be done [1, 2, 5, 6, 12, 15-17, 20, 21]. Furthermore, monitoring of the central nervous system and renal functions should be performed. Chelating therapy and psychiatric consultation should be applied when indicated [1, 5, 12, 15, 16, 20, 28].

Otherwise, it is difficult to predict if chronic intoxication will develop following subcutaneous and intramuscular injection. Ellabban et al. [1] reported that subcutaneous deposition of mercury does not carry the systemic risk associated with mercury inhalation. Nevertheless, Chodorowski et al. [29] reported two deaths secondary to renal failure and pulmonary empyema [15, 17]. On the other hand, Davey and Benson [21] suggest that the chronic phase of metallic mercury intoxication following intravenous injection seems to be benign, with low risk of developing long term neurological or pulmonary sequel.

In the present case, there have been no symptoms of mercury intoxication during a period of nearly 15 years of exposure. However, prolonged clinical and biochemical follow-up have to be performed [6, 12, 14, 16, 24], although it is known that there is no correlation between mercury levels in the blood and urine and the severity of symptoms in case of chronic poisoning [2, 28].

The usage of chelating agents (e.g. DMPS, dimercaprol (BAL), dimercaprosuccinic acid (DMSA), British Anti Lewisite (BAL), d-penicillamine) in the treatment of mercury intoxication is controversial [4, 5, 12-14, 21]. Sarikaya et al. [3] related the usage of N-acetyl cysteine (NAC) for chelating therapy, additionally. Maynou et al. [2], Krohn et al. [28], Ellabban et al. [1] and several others recommended the usage of chelation therapy if there are signs of systemic intoxication and following intravenous injection [4, 7, 8, 15, 16, 20]. On the other hand, Davey and Benson [21] suggest that the long term benefit of
chelation therapy is equally low in case of chronic mercury poisoning and therefore the usage should be restricted to acute intoxication. Lim et al. [13] reported a decrease of serum mercury concentration using chelation therapy but it has no effect on progression of acute lung injury.

In the present case, chelating therapy with DMPS was introduced due to the recommendation by the local centre for intoxications, although there were no signs of systemical poisoning. Furthermore, haemodialysis and plasma exchange are only indicated if renal failure occurs combined with anuria [4, 18, 19]. Alhamad et al. [4] related that chelator-mercury complexes are only dialyzable using larger pore dialysis membranes. Nevertheless, Yoshida et al. [19] suggested that renal damages due to acute mercury poisoning may not be permanent.

**Conclusion:**

Blood levels of mercury will decrease rapidly following surgery combined with chelating therapy. Subcutaneous and intramuscular injection of metallic mercury requires marginal or wide excision of all contaminated tissue to prevent migration of mercury and chronic inflammation or intoxication. Nevertheless, prolonged clinical and biochemical monitoring should be performed for several years to screen for chronic intoxication.
Informed Consent:

Written informed consent was obtained from the patient for publication of this case report and any accompanying images. A copy of the written consent is available for review by the Editor-in-Chief of this journal.

Competing interests:

The authors declare that they have no competing interests.

Authors' contributions

JF and WME acquired the data and wrote the manuscript, ET and PS performed the clinical follow-up of the patient, AL and WME performed the surgery. Furthermore, all authors have been involved in drafting the manuscript or revising it critically for important intellectual content read and approved the final manuscript.
