Abstract

Background: Cerebrospinal fluid (CSF) biological markers may be of valuable for help in the diagnosis of Alzheimer's disease (AD). The prospect of early detection and treatment, to slow progression, holds hope for aging populations with increased average lifespan. The aim of the present study was to investigate candidate CSF biological markers in patients with mild cognitive impairment (MCI) and AD and compare them with age-matched normal control subjects.

Methods: We applied clinical proteomics to 60 CSF samples and focused our investigation on the quantitative change of protein biomolecules with progression of AD. We classified patients by three groups: normal controls without cognitive dysfunction, MCI and AD. The AD group was subdivided into three groups by clinical severity according to a well known clinical scale for dementia, clinical dementia rating (CDR).

Results: We demonstrated a gradual increase in CSF fibrinogen gamma-A chain precursor protein in patients with mild cognitive impairment and AD compared to the age-matched control subjects. The CSF-fibrinogen gamma-A chain precursor protein was elevated in the MCI group; its expression was more prominent in the AD group, and correlated with disease severity and progression. The expression level of fibrinogen gamma-A chain precursor protein was observed to be very weak in age-matched control
subjects.

**Conclusion:** These findings suggest that the CSF level of fibrinogen gamma-A chain precursor may be a candidate biomarker for the progression of MCI to AD.
Background

Neurodegenerative diseases are characterized by chronic, progressive, irreversible deterioration of neurological function affecting cognition and motor-sensory functions, resulting in independent living. Diagnosis of neurodegenerative disease largely depends on clinical manifestations; patients usually present to clinicians when their symptoms interfere with activities of daily living (ADL). By the time patients present with these complaints, nerve cells have already been damaged irreversibly and progression of disease may be inevitable. For this reason, there is a need for a molecular-based diagnostic marker in biologic fluids that can identify neurodegenerative disease at an early or preclinical phase; this diagnostic marker could be a disease-modifying compound targeted to drug development [1].

Biochemical changes in the brain are well reflected in the CSF which is in direct contact with the brain extracellular space. Furthermore since brain metabolites that pass into the plasma become markedly diluted CSF may be an obvious source of biomarkers for neurodegenerative disease rather than plasma [2].

Biomarkers have been discussed as possible diagnostic tools but have not been frequently used in research on the elderly because of the general paucity of supportive scientific data. However, there is an obvious need for greater diagnostic specificity and
sensitivity across many diagnoses in the elderly, as well as good targets for therapeutic trials. Of the many possible areas for the discovery of biomarkers, the field of clinical proteomics is especially well suited for investigation of biomarkers in the CSF which contains proteins associated with brain functioning under healthy conditions as well as with several neurodegenerative diseases. Many studies have demonstrated proteins in CSF associated with neurodegenerative disease using proteomics. Of the many neurodegenerative diseases studied, Alzheimer’s disease (AD) is reported on most frequently [1, 3-7].

AD is the most prevalent neurodegenerative disease, the most common form of dementia and affects nearly 10% of the population after 65 years of age [8]. Like other neurodegenerative diseases the diagnosis of AD is based on clinical findings and progression of the disease together with exclusion of other causes of dementias; only the neuropathological findings confirm a definite diagnosis. Most of the diagnostic pathological characteristics include extracellular amyloid plaque and intracellular neurofibrillary tangle [9].

While some progress has been made in the search for adequate biomarkers in the elderly, in particular with AD, much more work is needed before these potential biomarkers can be reliably used in clinical practice. Previous studies infrequently have focused on
staging of the clinical phase of a disease and progression with neuropsychological investigations.

The objective of our study was to investigate a novel biomarker for diseases associated with memory disturbance including AD, which is one of the most prevalent neurodegenerative diseases, by applying clinical proteomics to CSF samples; we focused our investigation on the quantitative change of protein biomolecules with progression of disease.
Methods

Patient selection and grouping

During the study period from October 2004 to September 2005, a total of 60 subjects were enrolled at the Bobath Memorial Hospital. There were 30 individuals (mean age = 75.7 y, range 60 to 95) with clinically diagnosed neurodegenerative diseases and 30 age-matched normal control subjects (mean age = 73.2 y, range 61 to 95). None of the patients had other malignancies or active pulmonary disease. CSF from 60 subjects was obtained before therapy. All patients and controls were subjected to the analysis with individual consent for the study. The use of CSF samples was approved by the Ethics Committee of our institution. The diagnosis of probable AD was made according to criteria proposed by the National Institute of Neurological and Communicative Disorders and Stroke—Alzheimer’s Disease and Related Disorders Association (NINCDS-ADRDA) [10]. Differences in disease progression were evaluated using the clinical dementia rating (CDR) [11]. Because it is difficult to differentiate CDR 0.5 with 1 and CDR 3 with 4, 5, we arbitrary subdivided into three group: group 1 (CDR 0.5 and 1), group 2 (CDR 2), group 3 (CDR 3, 4 and 5). The subjects were classified according to whether they were controls with no cognitive deficit group or if they had mild cognitive impairment (MCI). The thirty controls were defined by both the absence of
significant cognitive impairment and absence of AD or other significant neuropathology. The patients without dementia, the control group, consisted of patients with other complaints such as back pain and headache. Neuropsychological testing was performed on all participants to confirm their cognitive status.

**CSF samples**

CSF was obtained by lumbar puncture from individuals. The stage of disease at the time of lumbar puncture was variable. Ten ml of CSF was obtained and aliquoted into samples of 1 ml each; then they were shipped on dry ice and stored at -70°C until needed.

**Two-dimensional gel electrophoresis**

Briefly, 125 µl aliquots of CSF (containing approximately 50 µg of protein) were precipitated overnight at -20°C using ice-cold ethanol. The resulting protein pellet was dissolved in 125 µl of 7 M urea, 2 M thiourea, 4% CHAPS, 60 mM dithiothreitol, 0.5% carrier ampholytes and a trace of bromophenol blue. The sample was then hydrated directly into commercially available pH 4-7 nonlinear immobilized pH gradient (IPG) isoelectric focusing gels (Amersham Biosciences, Piscataway, NJ). The first dimension
of separation, isoelectric focusing, was then performed at 20°C using the IPGphor isoelectric focusing unit (Amersham Pharmacia Biotec, CA) for a total of 75 kVh. The IPG gels were equilibrated in solutions containing dithiothreitol for reduction and then iodoacetamide for alkylation. The second dimension of separation, polyacrylamide gel electrophoresis, was then performed using 12 %T acrylamide slab gels. Next, 2 DE gels were stained with silver nitrate for mass spectrometry analysis and confirmation of proteins that existed in low abundant spots [12]. Gels were fixed overnight in 30% ethanol, 10% acetic acid and washed with 20% ethanol for 20 min. The gels were sensitized for 1 min in 0.02% sodium thiosulfate and than the gels were incubated in 0.2% silver nitrate for 45 min. Development of protein spots were in 3% potassium carbonate, 0.025% formaldehyde, 0.001% sodium thiosulfate and were scanned on a GS-800 Calibrated Densitometer (Bio-Rad Laboratories, Seoul, Korea). Gels were run in duplicate and spots were selected that appeared consistently in all of the runs.

**In-gel digestion**

We excised 1mm cutting diameter protein spots to analyze. In-gel digestion was then performed according to protocols previously described [13]. Briefly, gel plugs were destained with solution mix of 30 mM potassium ferricyanide and 100 mM sodium
thiosulfate by 1:1 (v/v); the gel plugs were washed 3 times for 15 min in distilled water. Destained gel plugs were shrank by 50 mM ammonium bicarbonate, acetonitrile and then dried down in a vacuum centrifuge. The proteins were then reduced and alkylated using solutions of 10 mM dithiothreitol and 100 mM iodoacetamide. Gel plugs were washed with 50 mM ammonium bicarbonate and dried with acetonitrile which were then rehydrated with a solution of trypsin (sequencing grade; Promega, Madison, WI) (5 µg/ml). The digestion process was performed overnight at 37°C and was stopped by addition of 3% formic acid. For some low-concentration spots, two or three gel plugs were digested together to increase the peptide yield. Samples were crystallized onto a MTB AnchorChip TM 600/384 (Bruker Daltonik GmbH, Leipzig, Germany) MALDI plate using the dried droplet method. For the matrix, a solution of 20 µg/µl α-cyano-4-hydroxycinnamic acid (CHCA) in 0.1% triflouroacetic acid / ACN (v/v = 70:30) was used. CHCA matrix solution was diluted 10 times with ethanol/acetone (v/v = 70:30) and then peptides samples were diluted 10 times in CHCA matrix solution.

**MS analysis**

Linear and reflectron MALDI-TOF mass spectra were acquired on an Ultraflex mass spectrometer (Bruker Daltonik). Positive ion spectra were recorded using aluminum
sample holders with standard parameter; a nitrogen laser (\( \lambda = 337 \) nm), 39 ns pulse duration and 20 kV for accelerating voltage. Peptide mass fingerprint data were collected in the positive MS reflector mode in the range of 500-4000 mass-to-charge ratio (m/z) using 1000-3000 laser shots for each sample and were calibrated internally using trypsin autolysis peaks. The spectra were analyzed using flexAnalysis (Version 2.2, Bruker Daltonik GmbH), which acts as an interface between the BioTools (Version 2.2, Bruker Daltonik) database containing raw spectra and a local copy of the Mascot search engine [http://www.matrixscience.com]. The MS data were searched together against a locally stored copy of the NCBInr human protein database [http://www.ncbi.nlm.nih.gov] using the Mascot search engine. The search allowed for up to one missed trypsin cleavage site, oxidation of methionine, and carbamidomethylation of cysteine.
Results

Expression patterns of CSF protein spots in normal, MCI and AD

Figure 1 shows 2-DE images of gels from the CSF samples of normal control, MCI, and AD (group 1, 2, and 3). On gels loaded with 50 µg of the CSF sample, 350 spots were detected. A visual comparison of spot patterns on the 2-DE gels from the CSF samples changed gradually in MCI, AD compared to normal controls. Although the individual spot intensities change between samples, the spot patterns are very similar. All CSF samples that are used in this experiment, to analyze relative differential expression, used all proteins including albumin and IgG.

Identification of a novel candidate protein whose expression in CSF is altered relative to normal controls

We analyzed the differential protein expression of AD patient’s CSF samples, to find candidates for AD-associated proteins; selective protein identification was performed by peptide mass fingerprinting with delayed extraction-matrix assisted laser desorption/ionization-time of flight-mass spectrometry (DE-MALDI-TOF-MS). Their identification baseline was noted first, with a high Mascot score more than 67 points, and second, with a molecular weight and pI value similar to identified proteins, and finally with a high coverage from identified protein full sequence.
In total, two over-expressed protein spots were identified (Figure 2). These arrow marked spots about 50 kDa were two spots identified by a fibrinogen gamma-A chain precursor. The details data for the identified protein is described in Table 1.

**Fibrinogen gamma-A chain precursor**

Fibrinogen gamma-A chain precursor expression was observed to gradually increase according to progression of disease and showed the highest expression in the last step of group 3. The clinical feature of group 3 is characterized by end stage of dementia symptoms including severely impaired memory and cognition, devastated personal, which result in totally dependent activities of daily living. The two spots were found in all five patients and the molecular weight was about 50 kDa. A pI of 5.6 was also noted, and confirmed a very high reproduction in a repeated experiment (Figure 3).
Discussion

The diagnosis of AD commonly relies on excluding other disorders with similar clinical features. To facilitate an early diagnosis, additional diagnostic tools related to causes of neuronal degeneration would be of great interest [14]. Such molecules that have been shown to be associated with AD are free radicals and oxidative stress promoting molecules, proinflammatory cytokines and neurotoxic agents [15]. Most of these biomarker molecules are studied in the blood and may not reflect central pathologic processes occurring in the brain of patients with AD. Therefore, CSF is a more suitable biological fluid for study of biomarker molecules in AD. Of the many potential areas for study of CSF, the field of clinical proteomics is especially well suited for discovery of biomarkers in CSF; this is because proteins are abundant in CSF [14].

Proteomics has emerged in the last few years as a multidisciplinary and technology-driven science that focuses on proteomes: the complex of proteins expressed in biological systems, their structures, interactions and post-translational modifications. In particular, proteomics examines changes in protein levels and other protein alterations that result from or foster specific diseases, or are affected by various external factors, such as toxic agents.

The combination of immunoassays and proteomic methods show that CSF proteins
express differential protein patterns in AD, frontotemporal dementia (FTD), and PD patients; these findings suggest divergent underlying pathophysiological mechanisms and neuropathological changes underlying these diseases.

Potential biomarkers with pathophysiologic significance have been studied in the field of AD research with some success, especially in the area of genetic markers (apolipoprotein E epsilon4 allele), neuroimaging, and cerebrospinal fluid markers (Aβ42 and tau). Of these, results using proteomics combined with immunochemical studies are the most abundant. To date, combined clinical examinations and measurement of the biochemical markers (β-amyloid and tau) in CSF have become valuable diagnostic tools for predicting more than 80% of AD cases [16]. Other proteins known to be associated with AD pathology are apolipoprotein E (apo E) and synaptic proteins which have been studied by immunoassays [15]. Other candidate CSF biomarkers include: ubiquitin [17], NF protein [18], GAP43 (neuromodulin) [5, 19, 20] and NTP and AD7c protein [21-23]. An increasing number of studies suggest that supplementary use of these CSF markers preferably in combination, adds to the accuracy of AD diagnosis [16].

Fibrinogen gamma chain (FGG) is the gamma component of fibrinogen, a blood-borne glycoprotein comprised of three pairs of non-identical polypeptide chains. FGG A
precursor is one of the transcript variant isoforms due to alternative splicing [24].

The functional features of the FGG include participation in fibrin polymerization and cross-linking, the initiation of fibrinolysis, a role in binding and regulating factor XIII activity, high affinity binding sites for integrin of platelets, leukocyte, and a role in mediating thrombin binding to fibrin, an inhibitory function originally termed ‘antithrombin I’ [25].

It is well known that hemostatic factors and inflammatory proteins are closely related to atherosclerosis and cardiovascular risk [26, 27]. An additional hypothesis is that these factors might be related to vascular dementia. There are many reports that have discussed this relationship [28]. However, there is limited evidence, and a paucity of information, on hemostatic markers for AD. Moreover, although there are reports on the association of AD with fibrinogen in blood [29, 30], there is no information of such an association in CSF.

In our study, fibrinogen gamma-A chain precursor was found to be increased in expression in both MCI and AD patients compared to normal controls. This expression was more prominent in AD patients than in both the normal controls and the MCI group, and appeared to be related to the severity of dementia. Although we cannot explain the actual relationship between FGG and AD at this point in time, these findings suggest
that activated fibrinogen gamma-A chain precursor may be an important marker for the progression of MCI to AD and an important factor in the severity of AD.
Conclusion

In conclusion we present that suggests activated fibrinogen gamma-A chain precursor may be an important marker for the progression of MCI to AD and an important factor in the severity of AD. Further study is needed to confirm these findings and to improve the understanding of the relationship between FGG, mild cognitive impairment and AD.
